# **Chapter Four**

# 4. Arrays and Strings

#### 4.1. Introduction

Variables in a program have values associated with them. During program execution these values are accessed by using the identifier associated with the variable in expressions etc. In none of the programs written so far have very many variables been used to represent the values that were required. Thus even though programs have been written that could handle large lists of numbers it has not been necessary to use a separate identifier for each number in the list. This is because in all these programs it has never been necessary to keep a note of each number individually for later processing. For example in summing the numbers in a list only one variable was used to hold the current entered number which was added to the accumulated sum and was then overwritten by the next number entered. If that value were required again later in the program there would be no way of accessing it because the value has now been overwritten by the later input.

If only a few values were involved a different identifier could be declared for each variable, but now a loop could not be used to enter the values. Using a loop and assuming that after a value has been entered and used no further use will be made of it allows the following code to be written. This code enters six numbers and outputs their sum:

This of course is easily extended to n values where n can be as large as required. However if it was required to access the values later the above would not be suitable. It would be possible to do it as follows by setting up six individual variables:

```
float a, b, c, d, e, f;
```

and then handling each value individually as follows:

```
sum = 0.0;
cin >> a; sum += a;
cin >> b; sum += b;
cin >> c; sum += c;
cin >> d; sum += d;
cin >> e; sum += e;
cin >> f; sum += f;
```

which is obviously a very tedious way to program. To extend this solution so that it would work with more than six values then more declarations would have to be added, extra assignment statements added and the program re-compiled. If there were 10000 values imagine the tedium of typing the program (and making up variable names and remembering which is which)!

To get round this difficulty all high-level programming languages use the concept of a data structure called an **Array**.

# 4.2. What is an arrays

An **array** is a data structure which allows a collective name to be given to a group of elements which <u>all have the same type</u>. An individual element of an array is identified by its own unique <u>index</u> (or **subscript**).

An array can be thought of as a collection of numbered boxes each containing one data item. The number associated with the box is the index of the item. To access a particular item the index of the box associated with the item is used to access the appropriate box. The index **must** be an integer and indicates the position of the element in the array. Thus the elements of an array are **ordered** by the index.

# 4.3. One Dimensional Array

## **4.3.1. Declaration of Arrays**

An array declaration is very similar to a variable declaration. First a type is given for the elements of the array, then an identifier for the array and, within square brackets, the number of elements in the array. The number of elements **must be an integer**.

For example data on the average temperature over the year in Ethiopia for each of the last 100 years could be stored in an array declared as follows:

```
float annual_temp[100];
```

This declaration will cause the compiler to allocate space for 100 consecutive float variables in memory. The number of elements in an array must be fixed at compile time. It is best to make the array size a constant and then, if required, the program can be changed to handle a different size of array by changing the value of the constant,

```
const int NE = 100;
float annual temp[NE];
```

then if more records come to light it is easy to amend the program to cope with more values by changing the value of NE. This works because the compiler knows the value of the constant NE at compile time and can allocate an appropriate amount of space for the array. It would not work if an ordinary variable was used for the size in the array declaration since at compile time the compiler would not know a value for it.

# 4.3.2. Accessing Array Elements

Given the declaration above of a 100-element array the compiler reserves space for 100 consecutive floating point values and accesses these values using an index/subscript that takes values from 0 to 99. The <u>first element</u> in an array in C++ always has the <u>index 0</u>, and if the array has n elements the <u>last</u> element will have the <u>index n-1</u>.

An **array element** is accessed by writing the identifier of the array followed by the subscript in square brackets. Thus to set the 15th element of the array above to 1.5 the following assignment is used:

```
annual temp[14] = 1.5;
```

Note that since the first element is at index 0, then the <u>ith</u> element is at <u>index</u> <u>i-1</u>. Hence in the above the 15th element has index 14.

An array element can be used anywhere an identifier may be used. Here are some examples assuming the following declarations:

A value can be read into an array element directly, using cin

```
cin >> count[i];
```

The element can be increased by 5,

```
count[i] = count[i] + 5;
```

or, using the shorthand form of the assignment

```
count[i] += 5;
```

Array elements can form part of the condition for an if statement, or indeed, for any other logical expression:

for statements are the usual means of accessing every element in an array. Here, the first NE elements of the array annual\_temp are given values from the input stream cin.

```
for (i = 0; i < NE; i++)
  cin >> annual temp[i];
```

The following code finds the average temperature recorded in the first ten elements of the array.

```
sum = 0.0;
for (i = 0; i <10; i++)
    sum += annual_temp[i];
av1 = sum / 10;</pre>
```

Notice that it is good practice to use named constants, rather than literal numbers such as 10. If the program is changed to take the average of the first 20 entries, then it all too easy to forget to change a 10 to 20. If a const is used consistently, then changing its value will be all that is necessary.

For example, the following example finds the average of the last k entries in the array. k could either be a variable, or a declared constant. Observe that a change in the value of k will still calculate the correct average (provided k<=NE).

```
sum = 0.0;
for (i = NE - k; i < NE; i++)
  sum += annual_temp[i];
av2 = sum / k;</pre>
```

Important - C++ does not check that the subscript that is used to reference an array element actually lies in the subscript range of the array. Thus C++ will allow the assignment of a value to annual\_temp[200], however the effect of this assignment is unpredictable. For example it could lead to the program attempting to assign a value to a memory element that is outside the program's allocated memory space. This would lead

to the program being terminated by the operating system. Alternatively it might actually access a memory location that is within the allocated memory space of the program and assign a value to that location, changing the value of the variable in your program which is actually associated with that memory location, or overwriting the machine code of your program. Similarly reading a value from annual\_temp[200] might access a value that has not been set by the program or might be the value of another variable. It is the programmer's responsibility to ensure that if an array is declared with n elements then no attempt is made to reference any element with a subscript outside the range 0 to n-1. Using an index, or subscript, that is out of range is called Subscript Overflow. Subscript overflow is one of the commonest causes of erroneous results and can frequently cause very strange and hard to spot errors in programs.

## 4.3.3. Initialization of arrays

The initialization of simple variables in their declaration has already been covered. An array can be initialized in a similar manner. In this case the initial values are given as a list enclosed in curly brackets. For example initializing an array to hold the first few prime numbers could be written as follows:

```
int primes[] = {1, 2, 3, 5, 7, 11, 13};
```

Note that the array has not been given a size, the compiler will make it large enough to hold the number of elements in the list. In this case primes would be allocated space for seven elements. If the array is given a size then this size must be greater than or equal to the number of elements in the initialization list. For example:

```
int primes[10] = \{1, 2, 3, 5, 7\};
```

would reserve space for a ten element array but would only initialize the first five elements.

Example Program: Printing Outliers in Data

The requirement specification for a program is:

A set of positive data values (200) are available. It is required to find the average value of these values and to count the number of values that are more than 10% above the average value.

Since the data values are all positive a negative value can be used as a sentinel to signal the end of data entry. Obviously this is a problem in which an array must be used since the values must first be entered to find the average and then each value must be compared with this average. Hence the use of an array to store the entered values for later re-use.

An initial algorithmic description is:

```
initialize.
    enter elements into array and sum elements.
    evaluate average.
    scan array and count number greater than
                            10% above average.
    output results.
This can be expanded to the complete algorithmic description:
    set sum to zero.
    set count to zero.
    set nogt10 to zero.
    enter first value.
    while value is positive
        put value in array element with index count.
        add value to sum.
        increment count.
        enter a value.
    average = sum/count.
    for index taking values 0 to count-1
        if array[index] greater than 1.1*average
            then increment nogt10.
    output average, count and nogt10.
```

In the above the variable nogt10 is the number greater than 10% above the average value. It is easy to argue that after exiting the while loop, count is set to the number of positive numbers entered. Before entering the loop count is set to zero and the first number is entered, that is count is one less than the number of numbers entered. Each time round the loop another number is entered and count is incremented hence count remains one less than the number of numbers entered. But the number of numbers entered is one greater than the number of positive numbers so count is therefore equal to the number of positive numbers.

A main () program written from the above algorithmic description is given below:

```
void main()
{
  const int NE = 200;  // maximum no of elements in array
  float sum = 0.0;  // accumulates sum
  int count = 0;  // number of elements entered
  int nogt10 = 0;  // counts no greater than 10%
```

```
// above average
                    // holds each no as input
float x;
                   // array to hold input
float indata[NE];
float average;
                    // average value of input values
                     // control variable
int i;
    // Data entry, accumulate sum and count
   // number of +ve numbers entered
cout << "Enter numbers, -ve no to terminate: " << endl;</pre>
cin >> x;
while (x >= 0.0)
   sum = sum + x;
   indata[count] = x;
   count = count + 1;
   cin >> x;
  }
    // calculate average
average = sum/count;
   // Now compare input elements with average
for (i = 0; i < count; i++)
   if (indata[i] > 1.1 * average)
     nogt10++;
    // Output results
cout << "Number of values input is " << n;</pre>
cout << endl
     << "Number more than 10% above average is "
    << nogt10 << endl;
```

Since it was assumed in the specification that there would be less than 200 values the array size is set at 200. In running the program less than 200 elements may be entered, if n elements where n < 200 elements are entered then they will occupy the first n places in the array indata. It is common to set an array size to a value that is the maximum we think will occur in practice, though often not all this space will be used.

#### Example Program: Test of Random Numbers

The following program simulates the throwing of a dice by using a random number generator to generate integers in the range 0 to 5. The user is asked to enter the number of trials and the program outputs how many times each possible number occurred.

An array has been used to hold the six counts. This allows the program to increment the correct count using one statement inside the loop rather than using a switch statement

}

with six cases to choose between variables if separate variables had been used for each count. Also it is easy to change the number of sides on the dice by changing a constant. Because C++ arrays start at subscript 0 the count for an i occurring on a throw is held in the i-1th element of this count array. By changing the value of the constant die\_sides the program could be used to simulate a die\_sides-sided die without any further change.

```
#include <iostream.h>
#include <stdlib.h> // time.h and stdlib.h required for
#include <time.h> // random number generation
void main()
 const int die sides = 6;  // maxr-sided die
 int count[die sides];
                           // holds count of each
 float sample; // random fraction 0 .. 1
     // initialize random number generation and count
     // array and input no of trials
 srand(time(0));
 for (i=0; i < die sides; i++)
   count[i] = 0;
 cout << "How many trials? ";</pre>
 cin >> no trials;
     // carry out trials
 for (i = 0; i < no trials; i++)
     sample = rand()/float(RAND MAX);
     roll = int ( die sides * sample);
          // returns a random integer in 0 to die sides-1
     count[roll]++;  // increment count
   }
     // Now output results
 for (i = 0; i < die sides; i++)
     cout << endl << "Number of occurrences of "</pre>
          << (i+1) << " was " << count[i];
 cout << endl;</pre>
}
```

## 4.3.4. Copying Arrays

The assignment operator *cannot* be applied to array variables:

```
const int SIZE=10
int x [SIZE] ;
int y [SIZE] ;
```

```
x = y ; // Error - Illegal
```

Only individual elements can be assigned to using the index operator, e.g., x[1] = y[2];.

To make all elements in 'x' the same as those in 'y' (equivalent to assignment), a loop has to be used.

```
// Loop to do copying, one element at a time
for (int i = 0 ; i < SIZE; i++)
    x[i] = y[i];</pre>
```

This code will copy the elements of array y into x, overwriting the original contents of x. A loop like this has to be written whenever an array assignment is needed.

Notice the use of a constant to store the array size. This avoids the literal constant '10' appearing a number times in the code. If the code needs to be edited to use different sized arrays, only the constant needs to be changed. If the constant is not used, all the '10's would have to be changed individually - it is easy to miss one out.

## 4.4. Multidimensional arrays

An array may have more than one dimension. Each dimension is represented as a subscript in the array. Therefore a two dimensional array has two subscripts, a three dimensional array has three subscripts, and so on.

Arrays can have any number of dimensions, although most of the arrays that you create will likely be of one or two dimensions.

A chess board is a good example of a two-dimensional array. One dimension represents the eight rows, the other dimension represents the eight columns.

Suppose the program contains a class named square. The declaration of array named board that represents would be

```
Square board[8][8];
```

The program could also represent the same data with a one dimensional, 64-square array. For example, it could include the statement

```
Square board[64];
```

Such a representation does not correspond as closely to the real-world object as the two dimensional array, however.

Suppose that when the game begins. The king id located in the fourth position in the first row. Counting from zero that position corresponds to board[0][3] in the two dimensional array, assuming that the first subscript corresponds to the row, and the second to the column.

## 4.4.1. Initializing Multidimensional Arrays

To initialize a multidimensional arrays, you must assign the list of values to array elements in order, with last array subscript changing while the first subscript while the first subscript holds steady. Therefore, if the program has an array int theArray[5][3], the first three elements go int theArray[0]; the next three into theArray[1]; and so forth.

The program initializes this array by writing

for the sake of clarity, the program could group the initializations with braces, as shown below.

```
int theArray[5][3] = { \{1, 2, 3\}, \{4, 5, 6\}, \{7, 8, 9\}, \{10, 11, 12\}, \{13, 14, 15\} \};
```

The compiler ignores the inner braces, which clarify how the numbers are distributed.

Each value should be separated by comma, regardless of whither inner braces are include.

The entire initialization must set must appear within braces, and it must end with a semicolon.

#### 4.4.2. Omitting the Array Size

If a one-dimensional array is initialized, the size can be omitted as it can be found from the number of initializing elements:

```
int x[] = \{ 1, 2, 3, 4 \} ;
```

This initialization creates an array of four elements.

Note however:

```
int x[][] = \{ \{1,2\}, \{3,4\} \} ; // \text{ error is not allowed.}
and must be written
int x[2][2] = \{ \{1,2\}, \{3,4\} \} ;
```

## Example of multidimensional array

# 4.5. Strings representation and manipulation

String in C++ is nothing but a sequence of character in which the last character is the null character '\0'. The null character indicates the end of the string. Any array of character can be converted into string type in C++ by appending this special character at the end of the array sequence.

In C++ strings of characters are held as an **array of characters**, one character held in each array element. In addition a special **null character**, represented by `\0', is appended to the end of the string to indicate the end of the string. Hence if a string has n characters then it requires an n+1 element array (at least) to store it. Thus the character `a' is stored in a single byte, whereas the single-character string "a" is stored in two consecutive bytes holding the character `a' and the null character.

A string variable s1 could be declared as follows:

```
char s1[10];
```

The string variable s1 could hold strings of length up to nine characters since space is needed for the final null character. Strings can be initialized at the time of declaration just as other variables are initialized. For example:

```
char s1[] = "example";
char s2[20] = "another example"
would store the two strings as follows:
s1 |e|x|a|m|p|1|e|\0|
s2 |a|n|o|t|h|e|r| |e|x|a|m|p|1|e|\0|?|?|?|?|
```

In the first case the array would be allocated space for eight characters, that is space for the seven characters of the string and the null character. In the second case the string is set by the declaration to be twenty characters long but only sixteen of these characters are <a href="https://github.com/gaddisa">https://github.com/gaddisa</a>

set, i.e. the fifteen characters of the string and the null character. Note that the length of a string does not include the terminating null character.

## 4.5.1. String Output

A string is output by sending it to an output stream, for example:

```
cout << "The string s1 is " << s1 << endl;
would print
The string s1 is example
```

The setw(width) I/O manipulator can be used before outputting a string, the string will then be output right-justified in the field width. If the field width is less than the length of the string then the field width will be expanded to fit the string exactly. If the string is to be left-justified in the field then the setiosflags manipulator with the argument ios::left can be used.

## 4.5.2. String Input

When the input stream cin is used space characters, newline etc. are used as separators and terminators. Thus when inputting numeric data cin skips over any leading spaces and terminates reading a value when it finds a white-space character (space, tab, newline etc.). This same system is used for the input of strings, hence a string to be input cannot start with leading spaces, also if it has a space character in the middle then input will be terminated on that space character. The null character will be appended to the end of the string in the character array by the stream functions. If the string s1 was initialized as in the previous section, then the statement

Note that the last two elements are a relic of the initialization at declaration time. If the string that is entered is longer than the space available for it in the character array then C++ will just write over whatever space comes next in memory. This can cause some very strange errors when some of your other variables reside in that space!

To read a string with several words in it using cin we have to call cin once for each word. For example to read in a name in the form of a Christian name followed by a surname we might use code as follows:

The name would just be typed by the user as, for example, Ian Aitchison and the output would then be

#### The name entered was Ian Aitchison

```
Enter a string: Law is a bottomless pit.
You entered: Law
```

Where did the rest of the phrase go?

It turns the insertion operator >> consider a space to be a terminating character.

Thus it will read strings consisting of a single word, but anything typed after a space is thrown away.

To read text containing blanks we use another function, cin::get().

```
#include<iostream.h>
void main()
{
   const int max=80;
   char str[max];
   cout<<"\n Enter a string;";
   cin.get(str,max); // max avoid buffer overflow
   cout<<"\n You entered : "<<str;
}</pre>
```

#### Reading multiple lines

We have solved the problem of reading strings with embedded blanks, but what about strings with multiple lines? It turns out that the cin::get() function can take a third argument to help out in this situation.

This argument specifies the character that tells the function to stop reading. The default value of this argument is the **newline('\n')** character, but if you call the function with some other character for this argument, the default will be overridden by the specified character.

In the next example, we call the function with a dollar sign ('\$') as the third argument

now you can type as many lines of input as you want. The function will continue to accept characters until you enter the terminated character \$ (or untill you exceed the size of the array. Remember, you must still press Enter key after typing the '\$' character.

## 4.5.3. Avoiding buffer over flow

The strings in the program invites the user to type in a string. What happens if the user enters a string that is longer than the array used to hold it? There is no built-in mechanism in C++ to keep a program from inserting array elements outside an array.

However, it is possible to tell the >> operator to limit the number of characters it places in an array.

```
//avoids buffer overflow with cin.width
#include<iostream.h>
#include<iomanip.h> //for setw
void main() {
  const int MAX=20;
  char str[MAX];
  cout<<"\n Enter a string: ";
  cin>>setw(MAX)>>str;
  cout<<"\n You entered :"<<str;
}</pre>
```

#### 4.5.4. String constants

You can initialize a string to a constant value when you define it. Here's an example'

```
#include<iostream.h>
void main() {
  char str[] = "Welcome to C++ programming language";
  cout<<str;
}</pre>
```

if you tried to the string program with strings that contain more than one word, you may have unpleasant surprise. Copying string the hard way

The best way to understand the true nature of strings is to deal with them character by character

```
#include<iostream.h>
#include<string.h> //for strlen()
void main()
{
  const int max=80;
  char str1[]='' Oh, Captain, my Captain!"
        our fearful trip is done";
  char str2[max];
  for(int i=0; i<strlen(str1);i++)
  str2[i]=str1[1];
  str2[i]='\0';
  cout<<end1;
  cout<<str2;
}</pre>
```

## 4.5.5. Copying string the easy way

Ofcourse you don't need to use a **for** loop to copy a string. As you might have guesses, a library function will do it for you. You can copy strings using **strcpy** or **strncpy** function. We assign strings by using the string copy function **strcpy**. The prototype for this function is in **string.h**.

```
strcpy(destination, source);
```

**strcpy** copies characters from the location specified by source to the location specified by destination. It stops copying characters after it copies the terminating null character.

o The return value is the value of the destination parameter.

You must make sure that the destination string is large enough to hold all of the characters in the source string (including the terminating null character).

## Example:

```
#include <iostream.h>
#include <string.h>
    void main() {
        char me[20] = "David";
        cout << me << endl;
        strcpy(me, "YouAreNotMe");
        cout << me << endl;
        return;
}</pre>
```

There is also another function **strncpy**, is like **strcpy**, except that it copies only a specified number of characters.

```
strncpy(destination, source, int n);
```

It may not copy the terminating null character.

## Example

```
#include <iostream.h>
#include <string.h>
void main() {
    char str1[] = "String test";
    char str2[] = "Hello";
    char one[10];
    strncpy(one, str1, 9);
    one[9] = '\0';
    cout << one << endl;
    strncpy(one, str2, 2);
    cout << one << endl;
    strcpy(one, str2);
    cout << one << endl;
    strcpy(one, str2);
    cout << one << endl;
}</pre>
```

## 4.5.6. Concatenating strings

In C++ the + operator cannot normally be used to concatenate string, as it can in some languages such as BASIC; that is you can't say

```
Str3 = str1 + str2;
```

You can use strcat() or strncat

The function streat concatenates (appends) one string to the end of another string.

```
strcat(destination, source);
```

- The first character of the source string is copied to the location of the terminating null character of the destination string.
- o The destination string must have enough space to hold both strings and a terminating null character.

#### Example:

```
#include <iostream.h>
#include <string.h>

void main() {
   char str1[30];
   strcpy(str1, "abc");
   cout << str1 << endl;
   strcat(str1, "def");
   cout << str1 << endl;

char str2[] = "xyz";
   strcat(str1, str2);</pre>
```

```
cout << str1 << endl;
str1[4] = '\0';
cout << str1 << endl;
}</pre>
```

The function strncat is like strcat except that it copies only a specified number of characters.

strncat(destination, source, int n);
It may not copy the terminating null character.

#### Example:

```
#include <iostream.h>
    #include <string.h>
    void main() {
        char str1[30];
        strcpy(str1, "abc");
        cout << str1 << endl;
        strncat(str1, "def", 2);
        str1[5] = '\0';
        cout << str1 << endl;
        char str2[] = "xyz";
        strcat(str1, str2);
        cout << str1 << endl;
        str1[4] = '\0';
        cout << str1 << endl;
        str1[4] < endl;
}</pre>
```

## 4.5.7. Comparing strings

Strings can be compared using strcmp or strncmp functions

The function stremp compares two strings.

cout << strcmp("abc", "ABC") << endl;</pre>

The function **strncmp** is like **strcmp** except that it compares only a specified number of characters.

```
strncmp(str1, str2, int n);
```

**strncmp** does not compare characters after a terminating null character has been found in one of the strings.

## **Example:**

```
#include <iostream.h>
#include <string.h>
void main()
{
  cout << strncmp("abc", "def", 2) << endl;
  cout << strncmp("abc", "abcdef", 3) << endl;
  cout << strncmp("abc", "abcdef", 2) << endl;
  cout << strncmp("abc", "abcdef", 5) << endl;
  cout << strncmp("abc", "abcdef", 5) << endl;
  cout << strncmp("abc", "abcdef", 20) << endl;
}</pre>
```

#### 4.6. Pointers

we can write:

A pointer is simply the *address* of a memory location and provides an indirect way of accessing data in memory. A pointer variable is defined to 'point to' data of a specific type. For example:

```
int *ptr1;  // pointer to an int
char *ptr2;  // pointer to a char
```

The *value* of a pointer variable is the address to which it points. For example, given the definitions

```
int num;
```

```
ptr1 = #
```

The symbol & is the **address** operator; it takes a variable as argument and returns the memory address of that variable. The effect of the above assignment is that the address of num is assigned to ptrl. Therefore, we say that ptrl points to num. Figure 5.**Error! Bookmark not defined.** illustrates this diagrammatically.

Given that ptr1 points to num, the expression

```
*ptr1
```

dereferences ptrl to get to what it points to, and is therefore equivalent to num. The symbol \* is the **dereference** operator; it takes a pointer as argument and returns the contents of the location to which it points.

In general, the type of a pointer must match the type of the data it is set to point to. A pointer of type void\*, however, will match any type. This is useful for defining pointers which may point to data of different types, or whose type is originally unknown. A pointer may be **cast** (type converted) to another type. For example,

```
ptr2 = (char*) ptr1;
```

converts ptr1 to char pointer before assigning it to ptr2.

Regardless of its type, a pointer may be assigned the value 0 (called the **null** pointer). The null pointer is used for initializing pointers, and for marking the end of pointer-based data structures (e.g., linked lists).  $\Box$ 

## 4.6.1. Dynamic Memory

In addition to the program stack (which is used for storing global variables and stack frames for function calls), another memory area, called the **heap**, is provided. The heap is used for dynamically allocating memory blocks during program execution. As a result, it is also called **dynamic memory**. Similarly, the program stack is also called **static memory**.

Two operators are used for allocating and deallocating memory blocks on the heap. The new operator takes a type as argument and allocated a memory block for an object of that type. It returns a pointer to the allocated block. For example,

```
int *ptr = new int;
char *str = new char[10];
```

allocate, respectively, a block for storing a single integer and a block large enough for storing an array of 10 characters.

Memory allocated from the heap does not obey the same scope rules as normal variables. For example, in

```
void Foo (void)
{
    char *str = new char[10];
    //...
}
```

when Foo returns, the local variable str is destroyed, but the memory block pointed to by str is *not*. The latter remains allocated until explicitly released by the programmer.

The delete operator is used for releasing memory blocks allocated by new. It takes a pointer as argument and releases the memory block to which it points. For example:

Note that when the block to be deleted is an array, an additional [] should be included to indicate this.

Should delete be applied to a pointer which points to anything but a dynamically-allocated object (e.g., a variable on the stack), a serious runtime error may occur. It is harmless to apply delete to the 0 pointer.

Dynamic objects are useful for creating data which last beyond the function call which creates them. Listing 5.1 illustrates this using a function which takes a string parameter and returns a *copy* of the string.

### Listing 5.1

```
#include <string.h>
char* CopyOf (const char *str)

char *copy = new char[strlen(str) + 1];

strcpy(copy, str);
return copy;
}
```

#### **Annotation (analysis)**

- 1 This is the standard string header file which declares a variety of functions for manipulating strings.
- The strlen function (declared in string.h) counts the characters in its string argument up to (but excluding) the final null character. Because the null character is not included in the count, we add 1 to the total and allocate an array of characters of that size.
- 5 The strcpy function (declared in string.h) copies its second argument to its first, character by character, including the final null character.

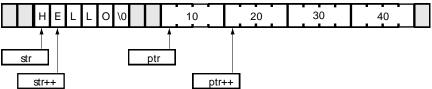

Because of the limited memory resources, there is always the possibility that dynamic memory may be exhausted during program execution, especially when many large blocks are allocated and none released. Should new be unable to allocate a block of the requested size, it will return 0 instead. It is the responsibility of the programmer to deal with such possibilities.

### 4.6.2. Pointer Arithmetic

In C++ one can add an integer quantity to or subtract an integer quantity from a pointer. This is frequently used by programmers and is called pointer arithmetic. Pointer arithmetic is *not* the same as integer arithmetic, because the outcome depends on the size of the object pointed to. For example, suppose that an int is represented by 4 bytes. Now, given

str++ advances str by one char (i.e., one byte) so that it points to the second character of "HELLO", whereas ptr++ advances ptr by one int (i.e., four bytes) so that it points to the second element of nums. Figure 5.1 illustrates this diagrammatically.

Figure 5.1 Pointer arithmetic.

It follows, therefore, that the elements of "HELLO" can be referred to as \*str, \*(str + 1), \*(str + 2), etc. Similarly, the elements of nums can be referred to as \*ptr, \*(ptr + 1), \*(ptr + 2), and \*(ptr + 3).

Another form of pointer arithmetic allowed in C++ involves subtracting two pointers of the same type. For example:

Pointer arithmetic is very handy when processing the elements of an array. Listing 5.2 shows as an example a string copying function similar to strcpy.

#### Listing 5.2

```
void CopyString (char *dest, char *src)

while (*dest++ = *src++)

;

}
```

#### Annotation

3 The condition of this loop assigns the contents of src to the contents of dest and then increments both pointers. This condition becomes 0 when the final null character of src is copied to dest.

In turns out that an array variable (such as nums) is itself the address of the first element of the array it represents. Hence the elements of nums can also be referred to using pointer arithmetic on nums, that is, nums[i] is equivalent to \* (nums + i). The difference between nums and ptr is that nums is a constant, so it cannot be made to point to anything else, whereas ptr is a variable and can be made to point to any other integer.

Listing 5.3 shows how the HighestTemp function (shown earlier in Listing 5.Error! Bookmark not defined.) can be improved using pointer arithmetic.

### Listing 5.3

#### **Annotation**

- Instead of passing an array to the function, we pass an int pointer and two additional parameters which specify the dimensions of the array. In this way, the function is not restricted to a specific array size.
- 6 The expression \*(temp + i \* columns + j) is equivalent to temp[i][j] in the previous version of this function.

HighestTemp can be simplified even further by treating temp as a one-dimensional array of row \* column integers. This is shown in Listing 5.4.

#### Listing 5.4

```
int HighestTemp (const int *temp, const int rows, const int columns)

int HighestTemp (const int *temp, const int rows, const int columns)

int HighestTemp (const int *temp, const int rows, const int columns)

for (register i = 0;
    i < rows * columns; ++i)
    if (*(temp + i) > highest)
        highest = *(temp + i);
    return highest;
}
```

#### **4.6.3. Function Pointers**

It is possible to take the address of a function and store it in a function pointer. The pointer can then be used to indirectly call the function. For example,

```
int (*Compare) (const char*, const char*);
```

defines a function pointer named Compare which can hold the address of any function that takes two constant character pointers as arguments and returns an integer. The string comparison library function strcmp, for example, is such. Therefore:

```
Compare = &strcmp; // Compare points to strcmp function
```

The & operator is not necessary and can be omitted:

```
Compare = strcmp; // Compare points to strcmp function
```

Alternatively, the pointer can be defined and initialized at once:

```
int (*Compare) (const char*, const char*) = strcmp;
```

When a function address is assigned to a function pointer, the two types must match. The above definition is valid because stremp has a matching function prototype:

```
int strcmp(const char*, const char*);
```

Given the above definition of Compare, strcmp can be either called directly, or indirectly via Compare. The following three calls are equivalent:

A common use of a function pointer is to pass it as an argument to another function; typically because the latter requires different versions of the former in different circumstances. A good example is a binary search function for searching through a sorted array of strings. This function may use a comparison function (such as stromp) for comparing the search string against the array strings. This might not be appropriate for all cases. For example, stromp is case-sensitive. If we wanted to do the search in a non-case-sensitive manner then a different comparison function would be needed.

As shown in Listing 5.5, by making the comparison function a parameter of the search function, we can make the latter independent of the former.

#### Listing 5.5

```
int BinSearch (char *item, char *table[], int n,
 1
 2
                   int (*Compare) (const char*, const char*))
 3
 4
        int bot = 0;
 5
        int top = n - 1;
 6
        int mid, cmp;
 7
        while (bot <= top) {
 8
            mid = (bot + top) / 2;
 9
            if ((cmp = Compare(item, table[mid])) == 0)
                                       // return item index
10
                return mid;
            else if (cmp < 0)
11
                                        // restrict search to lower half
12
               top = mid - 1;
13
            else
14
                bot = mid + 1;
                                        // restrict search to upper half
15
        }
16
                                         // not found
        return -1;
17
```

#### **Annotation**

- 1 Binary search is a well-known algorithm for searching through a *sorted* list of items. The search list is denoted by table which is an array of strings of dimension n. The search item is denoted by item.
- 2 Compare is the function pointer to be used for comparing item against the array elements.
- 7 Each time round this loop, the search span is reduced by half. This is repeated until the two ends of the search span (denoted by bot and top) collide, or until a match is found.
- 9 The item is compared against the middle item of the array.
- 10 If item matches the middle item, the latter's index is returned.
- 11 If item is less than the middle item, then the search is restricted to the lower half of the array.
- 14 If item is greater than the middle item, then the search is restricted to the upper half of the array.
- 16 Returns -1 to indicate that there was no matching item.

The following example shows how BinSearch may be called with strcmp passed as the comparison function:

```
char *cities[] = {"Boston", "London", "Sydney", "Tokyo"};
cout << BinSearch("Sydney", cities, 4, strcmp) << '\n';</pre>
```

This will output 2 as expected.

#### 4.6.4. References

A reference introduces an **alias** for an object. The notation for defining references is similar to that of pointers, except that & is used instead of \*. For example,

```
double num1 = 3.14;
double &num2 = num1;  // num is a reference to num1
```

defines num2 as a reference to num1. After this definition num1 and num2 both refer to the same object, as if they were the same variable. It should be emphasized that a reference does not create a copy of an object, but merely a symbolic alias for it. Hence, after

```
num1 = 0.16;
```

both num1 and num2 will denote the value 0.16.

A reference must always be initialized when it is defined: it should be an alias for something. It would be illegal to define a reference and initialize it later.

You can also initialize a reference to a constant. In this case a *copy* of the constant is made (after any necessary type conversion) and the reference is set to refer to the copy.

```
int \&n = 1; // n refers to a copy of 1
```

The reason that n becomes a reference to a copy of 1 rather than 1 itself is safety. Consider what could happen if this were not the case.

```
int &x = 1;
++x;
int y = x + 1;
```

The 1 in the first and the 1 in the third line are likely to be the same object (most compilers do constant optimization and allocate both 1's in the same memory location). So although we expect y to be 3, it could turn out to be 4. However, by forcing x to be a copy of 1, the compiler guarantees that the object denoted by x will be different from both 1's.

The most common use of references is for function parameters. Reference parameters facilitates the **pass-by-reference** style of arguments, as opposed to the **pass-by-value** style which we have used so far. To observe the differences, consider the three swap functions in Listing 5.6.

#### Listing 5.6

```
1
    void Swap1 (int x, int y)
                                     // pass-by-value (objects)
 2
 3
        int temp = x;
 4
        x = y;
 5
        y = temp;
 6
 7
    void Swap2 (int *x, int *y) // pass-by-value (pointers)
 8
 9
        int temp = *x;
10
        *x = *y;
        *y = temp;
11
12
13
    void Swap3 (int &x, int &y) // pass-by-reference
14
15
        int temp = x;
16
        x = y;
17
        y = temp;
18
```

#### **Annotation**

- 1 Although Swap1 swaps x and y, this has no effect on the arguments passed to the function, because Swap1 receives a *copy* of the arguments. What happens to the copy does not affect the original.
- 7 Swap2 overcomes the problem of Swap1 by using pointer parameters instead. By dereferencing the pointers, Swap2 gets to the original values and swaps them.
- 13 Swap3 overcomes the problem of Swap1 by using reference parameters instead. The parameters become aliases for the arguments passed to the function and therefore swap them as intended.

Swap3 has the added advantage that its call syntax is the same as Swap1 and involves no addressing or dereferencing. The following main function illustrates the differences:

```
int main (void)
{
   int i = 10, j = 20;
   Swap1(i, j);   cout << i << ", " << j << '\n';
   Swap2(&i, &j);   cout << i << ", " << j << '\n';
   Swap3(i, j);   cout << i << ", " << j << '\n';
}</pre>
```

When run, it will produce the following output:

```
10, 20
20, 10
10, 20
```

## 4.6.5. Typedefs

Typedef is a syntactic facility for introducing symbolic names for data types. Just as a reference defines an alias for an object, a typedef defines an alias for

a type. Its main use is to simplify otherwise complicated type declarations as an aid to improved readability. Here are a few examples:

```
typedef char *String;
Typedef char Name[12];
typedef unsigned int uint;
```

The effect of these definitions is that String becomes an alias for char\*, Name becomes an alias for an array of 12 chars, and uint becomes an alias for unsigned int. Therefore:

```
String str; // is the same as: char *str;
Namename; // is the same as: char name[12];
uintn; // is the same as: unsigned int n;
```

The complicated declaration of Compare in Listing 5.5 is a good candidate for typedef:

```
typedef int (*Compare) (const char*, const char*);
int BinSearch (char *item, char *table[], int n, Compare comp)
{
    //...
    if ((cmp = comp(item, table[mid])) == 0)
        return mid;
    //...
}
```

The typedef introduces Compare as a new type name for any function with the given prototype. This makes BinSearch's signature arguably simpler.
